Introduction

Reasoning for Addendum

The German FRL and the methods used are outlined in the NFAP. This document provides a more detailed description of the approach, shows data used and links to the documentation of a model that uses a comparable matrix to facilitate readers not familiar with this concept to better understand the mechanic of the calculations.

Reasoning for Corrigendum

Two tables presented in Annex I of the German NFAP did not reflect the correction of an attribution error in the National Forestry Inventory database carried out between the draft and the final calculation of the FRL (Table I-1 and I-4). Both are presented here in revised version. Table I-2 has been amended to enhance clarity about the rounding of the values. The new table has additional decimals for better understanding. Table I-5 lacked the separator at the thousands digits. This was fixed here, too.

Calculation of the forest area transition matrix and its use for construction of FRL biomass

The modelling of forest development over time is based on data from two subsequent forest inventories within the Reference Period, the reference years being 2002 and 2008. The same forest plots were measured in both inventories and were allocated in age classes and volume classes in both years (2002 and 2008). This forms an age class / volume class crosstable for each of these years. In the European Forestry Dynamics Model (EFDM), which was used as a blueprint to develop the German model, this is called a state-space.

The area distribution of the 2002 inventory is the starting point (see Table 1 which represents the corrected Table I-1 of Annex 1 to the NFAP).

Table 1: NFAP, Annex 1, Table I-1-corr: Area [kha] distribution of volume classes at the beginning of the RP (NFI 2002), rounded

A matrix is built showing which shares of area have moved from any given cell in 2002 to any other given cell in the following inventory in 2008 („transition vectors“, schematic illustration in Figure 1 below, data see Annex). The model is thus defined by the area distribution in the cells in 2002 and the set of vectors describing the area transition to respective cells in a five year period within the reference period, as observed in the two forest inventories.

This yields a huge data set of transition vectors from each cell of the age class / volume class cross table to another cell. The Annex contains a table with the complete set of transition vectors for all age and volume classes. They represent the share of area transitioning from each cell at the beginning to all cells during the 5-year period between 2002 and 2007.

In a stepwise five-yearly projection the crosstable for the area distribution is modelled.

Figure 1: Visualisation of transition vectors in the age class – volume class matrix

The assessed area distribution of the year 2008 is shown in Table 2.

Table 2: Area [kha] distribution of age and volume classes at the end of the RP (NFI subsample 2008)

age class [y]	volume class [m ³ ha ⁻¹]

From 2008 onwards, the same area transitions are repeated in five-year time steps to model future inventory intervals. The model applies the vectors at each step to the "new" distribution achieved by the previous modelling step. The areas in each cell of the state-space are split according to the transition vectors. The area in the „target cells“ is aggregated to derive the distribution of area at the subsequent simulated inventory date. The resulting distribution of forest area in the state-space thus describes the state of the forest after each time step. The resulting area distributions for the time steps 2012 (for transparency reasons only) is shown in Table 3. The 2017 matrix (as basis for 2018-2022) is shown in Table I-5 of Annex 1 of the NFAP and as same format (digits) as other tables here in Table 4, the one for 2022 (as basis for 2023-2027) is given in Table 5.

In contrast to EFDM, no further management activities are modelled. This results from the framework of the LULUCF Regulation which seeks to exclude any assumptions about changes in management practice after the reference period from the calculation of the FRL.

An average emission factor (EF, average net CO₂ emissions from biomass per hectare and year) for the projected time periods of 5 years is calculated by multiplying the EFs from the cells in the RP (Table I-2 of Annex 1 to the NFAP, amended version see Table 6) with the modelled areas for 2017 (see Table I-5 of the Annex I to the NFAP, s. Table 4 in this document), summing up and dividing the total by the total area behind the matrix model.

Table 6: NFAP, Annex 1, Table I-2 -amended: EFs [t CO₂-eq.ha⁻¹ a⁻¹] during the RP by forest classes, living biomass (trees, above- and belowground, rounded values)
